

METHOD FOR POWER CONTROL FOR MIXED VOICE AND DATA TRANSMISSION

BACKGROUND

5 1. FIELD OF THE INVENTION

The present invention generally relates to the field of wireless communication systems. More specifically, the invention relates to downlink, i.e. from the base station to a set of terminal units, mixed voice and data transmission for code division multiple access communication systems.

2. RELATED ART

In a code division multiple access (“CDMA”) communication system, such as IS-95, or CDMA2000, or WCDMA (wideband CDMA), transmission can be provided for voice communication and data communication simultaneously by transmitting voice and data signals across one or more communication channels. Certain types of signal transmission, for example, voice and certain types of low data rate data transmissions are degraded by delays in transmission. Certain types of data signal transmission, on the other hand, are tolerant of delays in transmission. For example, because the data is tolerant of delay, the data can be grouped into packets and scheduled for transmission. Furthermore, a delayed packet need not be dropped, and transmission errors can be corrected by simply retransmitting a packet at a later time, i.e. rescheduling the packet. Large amounts of packet data information can be transmitted efficiently in short “bursts” of data at high power and high data rate. Conventional voice/data transmission treats voice and data communications similarly by setting up a communication link at a pre-determined data rate, and attempting to transmit voice and data information without exceeding a certain frame error rate.

25

With conventional low data rate voice/data transmission, changes in the data rate generally do not involve significant changes in the overall transmit power; this is because low data rate connections only use a fraction of the total power available at the base station. By way of contrast, transmission of high speed packet data may require frequent extreme changes in data rate which typically involve large changes in power level. Since high data rate transmission uses a significant fraction of the total base station transmit power, the overall base station transmit power level could be significantly affected by the variation in the power used for high data rate transmissions.

In the present application, voice signal transmission and other signal transmission which is degraded by delays in transmission, as well as conventional data transmission where changes in the data rate are infrequent and relatively minor and changes in transmission power levels are small relative to the total base station transmit power, are referred to as "voice". Data signal transmission, such as high speed packet data, which can be tolerant of delays in transmission and can be scheduled, and typically is transmitted in short "bursts" at high power and high data rate, as well as any signal transmission where changes in the data rate are frequent and extreme and changes in transmission power levels are relatively large, are referred to as "data".

In order to efficiently accommodate these different types of signal transmission simultaneously, i.e., mixed voice and data transmission, different approaches may be followed. One approach is to specify a different part of the frequency spectrum, i.e. a different "band" of frequencies or frequency band, for each type of signal. Another approach is to multiplex the voice and data signals together through time division. With the time division approach, some of the time available for transmitting the

signals is allotted to voice signals and some of the time available for transmitting the signals is allotted to data signals. For example, in a GSM + GPRS system (Global System for Mobile combined with Generalized Packet Radio System) some time slots normally used for regular GSM voice transmission are instead used for packet data
5 transmission. One approach, used as an example in the present application, is code division multiple access (CDMA), which allows multiple signals to be transmitted at the same time on the same frequency band.

In CDMA systems each user's signal is separated from other users' signals by modulating the transmission signal with a distinct spreading code sequence. The modulation of the transmission signal spreads its spectrum so that the bandwidth of the encoded transmission signal is much greater than the original bandwidth of the user's information. For this reason CDMA is also referred to as "spread spectrum" modulation or coding. Each user uniquely encodes its information into a transmission signal using the spreading code sequence. The intended receiver, knowing the spreading code sequence of the user, can decode the transmission signal to recover the information.
10
15

By way of background, in CDMA communications, the user's signal is spread to allow many users to simultaneously use the same bandwidth without significantly interfering with one another. One means of spreading is the application of distinct
20 "orthogonal" spreading codes or functions, such as Walsh functions, to each user's signal. "Orthogonality" refers to lack of correlation between the spreading functions. In a given spread spectrum communication system using Walsh functions (also called Walsh code sequences), a pre-defined Walsh function matrix having n rows of n chips each is established in advance to define the different Walsh functions to be used to
25 distinguish different user's signals. As an example, for a given sector (or cell in the

WCDMA terminology), each downlink channel is assigned a distinct Walsh function. In other words, communications between a base station and each user are coded by a distinct Walsh code sequence in order to separate each user from the others.

The base station transmits signals to all users in a sector so that the Walsh codes are time synchronized in order to achieve orthogonality between the different signals. Effectiveness of the orthogonal spreading codes is affected by the phenomenon of “multipath”. Simply stated, multipath is interference caused by reception of the same signal over multiple paths, that is, multiple copies of the signal arrive after different path delays. Due to the loss of time synchronization, the orthogonality between different user signals is lost. Interference due to loss of orthogonality through multipath can be averaged by the use of other types of spreading codes such as pseudo-noise (“PN”) sequences, for example. The autocorrelation properties of PN sequences can be used to improve rejection of multipath interference. However, due to the loss of orthogonality through multipath, there is greater interference between the signals of different users, referred to as “intra-cell interference”, including interference of a user’s own signal with itself, also referred to as “self-interference”.

In a multi cell system, there can be interference caused by user signals transmitted by the base station in one cell interfering with the user signals transmitted in another cell, also referred to as “inter-cell interference”. The transmit power of the base station transmitters is controlled so as to minimize the amount of power transmitted into neighboring cells in order to limit inter-cell interference. Extreme fluctuations in transmit power can exacerbate the effects of inter-cell interference, as well as intra-cell interference between users including self-interference, described above.

Figure 1 illustrates an example of the effect of data transmission on power control for multiple voice and data users within the same cell in a CDMA or spread spectrum communication system. Figure 1 shows graph 100, having power axis 101 plotted against time axis 102. The transmit power for a typical voice user varies in time according to single user voice power curve 104. The aggregate transmission power for all the voice users within the cell is shown as P_v 106 in graph 100. Aggregate voice power P_v 106 varies in time as shown in graph 100. Power is allocated in addition to aggregate voice power P_v 106 for data burst transmissions 108, 109, and 110. The maximum available signal transmission power that can be allocated for the total of aggregate voice and data signal transmissions is maximum power limit P_{max} 112, shown in graph 100 as a horizontal solid line and also indicated by “ P_{max} .” The data and voice aggregate transmission power is shown as P_{v+d} 114 in graph 100. Data and voice aggregate power P_{v+d} 114 within the cell varies in time as shown in graph 100. As seen in graph 100, P_{v+d} 114 remains below maximum power limit P_{max} 112.

10
11
12
13
14
15

Figure 1 shows an example of the effect that data signal transmission can have on power control for a single user in terms of changes to single user voice power curve 104. As a result of data burst transmission 108, interference can be increased, due to the intra-cell effects outlined above, for the single user whose power allocation 20 is represented by single user voice power curve 104. To balance the increased interference, power allocation can be increased for the single user leading to local power peak 105 in single user voice power curve 104. In a conventional voice/data transmission system, changes in power allocation between users tend to balance out, by occurring randomly in time, leaving only a minor effect on aggregate voice power 25 P_v 106. However, the effect of data burst transmission 108 is simultaneous for many

users in the cell, so there is a relatively large effect on aggregate voice power P_v 106, shown as increase 116 in aggregate voice power P_v 106.

Continuing with Figure 1, at the end of data burst transmission 108, interference is reduced for the users within the cell. Thus, the power control system at 5 the base station will decrease the power allocation to the users, leading to decrease 117 in aggregate voice power P_v 106. In a mixed voice and data communication system, the power control system must be able to respond quickly to changes in interference. Thus, decrease 117 in aggregate voice power P_v 106 may be more than needed in view of subsequent data burst transmission 109. In other words, the reaction of the base station's power control system leading to decrease 117 "undershoots" the equilibrium value for stable system performance. As a result, then, of data burst transmission 109, which again causes an increase in interference for the users, the base station's power control system increases the power allocation for the users, leading to increase 118 in aggregate voice power P_v 106. Once again, increase 118 in aggregate voice power P_v 106 may be more than needed. In other words, the reaction of the power control system leading to increase 118 "overshoots" the equilibrium value for stable system performance.

Thus, as shown in Figure 1, when data signal transmission is mixed with voice signal transmission in a wireless communication system, the different signal characteristics of voice and data transmissions lead to problems with power control for 20 users within the same cell. The signal characteristics of data communications, namely that data transmission typically occurs in bursts, tends to cause disruptions in power control which do not occur with the relatively continuous signal characteristics of voice communications. For example, over-allocation and under-allocation of power to 25 each user and to the aggregate of all users within a cell can disrupt communications

and severely degrade the quality of the communication links. In addition, the system becomes subject to large swings in the total power output, as shown by the large variations in the level of data and voice aggregate power P_{v+d} 114, which indicates the total power output of the system.

5 Figure 2A, Figure 2B, and Figure 2C illustrate an example of some of the effects of data transmission on power control for users in neighboring cells in a CDMA or spread spectrum communication system. Figure 2A shows a diagram of cells for exemplary cellular spread spectrum communication system 200 comprising several cells including cell 203, labeled “cell #0” and cell 206, labeled “cell #1.” Despite the use of power control within each cell, out-of - cell terminal units cause interference which is not under the control of the receiving base station within the cell. Thus, for example, power control within cell 203 can be affected by interference from the transmission to terminal units in cell 206 and vice versa.

10 For example, in a mixed voice and data communication system, transmission of data within cell 203 can cause interference in a neighboring cell such as cell 206. The interference in cell 206 causes increased power allocation to terminal units in cell 206, which is in turn seen as increased interference in cell 203. The increased interference in cell 203 can cause increased power allocation in cell 203, which originally transmitted the data burst. Thus, there is a complete cycle of interaction between the
15 power allocation in cell 203 and cell 206, which resembles a positive feedback loop. The cycle of interaction between the power allocation in cell 203 and cell 206 can lead to higher power consumption than necessary in both cells. The increased power consumption in cell 203 and cell 206 can be seen as increased interference by other neighboring cells, so that the positive feedback effect spreads power control problems
20 from cell 203 and cell 206 to other cells in the system.
25

An example of feedback effect between two cells only, cell 203 and cell 206, is shown in detail in Figure 2B and Figure 2C. Figure 2B shows graph 230, having power axis 231 plotted against time axis 232. The total transmit power for voice users within cell 203 is shown as aggregate voice power P_v 236 in graph 230. Aggregate voice power P_v 236 varies in time as shown in graph 230. Power for data burst transmission 237 is allocated in addition to aggregate voice power P_v 236. Maximum power limit P_{max} 234 that is allocated for the total of aggregate voice and data transmissions in cell 203 is indicated in graph 230 by horizontal solid line P_{max} 234.

Figure 2C shows graph 260, having power axis 261 plotted against time axis 262. Time axis 262 of graph 260 is aligned vertically with time axis 232 of graph 230 so that points on time axis 262 in graph 260 align vertically below the simultaneous points on time axis 232 in graph 230. The total transmit power for voice users within cell 206 is shown as aggregate voice power P_v 266 in graph 260. Aggregate voice power P_v 266 varies in time as shown in graph 260. Maximum power limit P_{max} 264 that is allocated for the total of aggregate voice and data transmissions in cell 206 is indicated in graph 260 by horizontal solid line P_{max} 264.

Continuing with Figure 2B and Figure 2C, graph 230 of Figure 2B shows that the total transmit power within cell 203 is represented by aggregate voice power curve P_v 236, up until transmission of data burst 237. During data burst 237, the total transmit power within cell 203 is substantially equal to P_{max} 234. After data burst 237, the total transmit power within cell 203 is again represented by aggregate voice power curve P_v 236. Similarly, graph 260 of Figure 2C shows that the total transmit power within cell 206 is represented by aggregate voice power curve P_v 266. As discussed above, the power increase in cell 203, from P_v 236 to approximately P_{max} 234, during data burst 237 is seen as increased interference by the users within cell 206. The

increased interference in cell 206 leads to higher power allocation by the power control system in cell 206. The higher power allocation is reflected in increase 267 in aggregate voice power curve P_v 266. Conversely, increase 267 in aggregate voice power in cell 206 is seen as increased interference by the users within cell 203 and 5 leads to higher power allocation by the power control system in cell 203. The higher power allocation by the power control system in cell 203 is reflected in increase 238 in aggregate voice power curve P_v 236.

The feedback process continues back and forth between cell 203 and 206 and can lead to a cell allocating the maximum transmit power available, as shown, for example, by maximum 268 in aggregate voice power curve P_v 266. When all available transmit power has been allocated, such as at maximum 268 shown in graph 230 of Figure 2C, additional users can be denied access to the communication system. To the extent that additional users would have been able to access the communication system, system performance has been degraded. Further the communication link quality for the current users may also be degraded. As pointed out above, the effect can spread from cell to cell and is not restricted to the first pair of cells. Thus, Figure 2A, Figure 2B, and Figure 2C illustrate an example of some of the effects between cells of data transmission on power control in a CDMA or spread spectrum communication system.

As noted above, mixed transmission of voice and data in a CDMA or spread spectrum communication system can subject the system to large swings or variations in the amount of transmission power consumed. For example, such large variation is shown in Figure 1 by aggregate power curve P_{v+d} 114. As shown in Figure 1, P_{v+d} 114 varies from approximately one half of limit of maximum power P_{max} 112 to substantially all of P_{max} 112. Such large variation, comprising 50% of the maximum

power, would be typical for mixed voice and data communication systems where half of the available power is allocated for voice transmission and half of the available power is allocated for data transmission. As seen in Figure 1 and in Figure 2A, Figure 2B, and Figure 2C, the large variation can lead to over-allocation and under-allocation 5 of power to each user and to the aggregate of all users within one cell or several cells in the communication system. The resulting instability of power control in the communication system can cause serious degradation of system performance including access problems and degradation of communication link quality for the users.

Thus, there is a need in the art for transmitting mixed voice and data signals without causing abrupt large variations in power consumption. There is also a need in the art for transmitting mixed voice and data signals without causing sudden large reactions in power control. Further, there is need in the art for transmitting mixed voice and data signals without causing undue interference within a cell. Moreover, there is a need in the art for transmitting mixed voice and data signals without causing undue interference between cells.

SUMMARY

The present invention is directed to a method for power control for mixed voice 20 and data transmission. According to various embodiments of the invention, mixed voice and data signals are transmitted without causing abrupt large variations in power consumption or sudden large reactions in power control. Further, mixed voice and data signals are transmitted without causing undue interference within a cell or between cells.

25 In one aspect of the invention, a “voice noise power” is added to an aggregate

voice power which is the total voice power used by all users in a cell. The voice noise power is transmitted in addition to the aggregate voice power in order to maintain the total of the aggregate voice power and voice noise power at a pre-determined voice power limit. Since the aggregate voice power and the voice noise power are substantially maintained at a relatively steady level, i.e. at the voice power limit, power fluctuations within a cell and also in the neighboring cells are significantly diminished. The voice noise power can be, for example, artificial voice noise which is orthogonally coded or PN coded. In one embodiment, the voice power limit can be increased or decreased to further improve control over power consumption during voice and data transmission.

Further, in order to maintain the power consumed by data transmission at a desired level, data noise is transmitted after transmission of a data burst, or in between data bursts, by inserting a pre-determined amount of artificial data into the gaps in data transmission. The data noise is transmitted in addition to the data bursts in order to maintain the total power consumed during data transmission at a desired level. For example, the data noise can be transmitted as artificial noise or dummy data, which is orthogonally coded or PN coded. Since the total power consumed during data transmission is substantially maintained at a desired level, power fluctuations within a cell and also in the neighboring cells are significantly diminished. In one embodiment, the desired level for data transmission power consumption can be increased or decreased to further improve control over power consumption during voice and data transmission.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 illustrates an example of power control for mixed voice and data

transmission within one cell in a spread spectrum communication system.

Figure 2A illustrates an example diagram of geographical layout of cells for a spread spectrum communication system.

Figure 2B illustrates an example of power control graphed as a function of time
5 for cell number 0 of Figure 2A.

Figure 2C illustrates an example of power control graphed as a function of time, over the same time period as Figure 2B, for cell number 1 of Figure 2A.

Figure 3 illustrates an example of power control graphed as a function of time in accordance with one embodiment for a spread spectrum communication system.

Figure 4 also illustrates an example of power control graphed as a function of time in accordance with another embodiment for a spread spectrum communication system.

Figure 5 illustrates an example of power control graphed as a function of time in accordance with yet another embodiment for a spread spectrum communication system.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The presently disclosed embodiments are directed to a method for power control for mixed voice and data transmission. The following description contains specific information pertaining to the implementation of the present invention. One skilled in the art will recognize that the present invention may be implemented in a manner different from that specifically discussed in the present application. Moreover, some of the specific details of the invention are not discussed in order not to obscure the invention. The specific details not described in the present application
20 are within the knowledge of a person of ordinary skill in the art.
25

The drawings in the present application and their accompanying detailed description are directed to merely example embodiments of the invention. To maintain brevity, other embodiments of the invention which use the principles of the present invention are not specifically described in the present application and are not 5 specifically illustrated by the present drawings.

Figure 3 illustrates an example of power control in a CDMA communication system in accordance with one embodiment. The general principles of CDMA communication systems, and in particular the general principles for generation of spread spectrum signals for transmission over a communication channel is described in U.S. patent 4,901,307 entitled “Spread Spectrum Multiple Access Communication System Using Satellite or Terrestrial Repeaters” and assigned to the assignee of the present invention. The disclosure in that patent, i.e. U.S. patent 4,901,307, is hereby fully incorporated by reference into the present application. Moreover, U.S. patent 5,103,459 entitled “System and Method for Generating Signal Waveforms in a CDMA Cellular Telephone System” and assigned to the assignee of the present invention, discloses principles related to PN spreading, Walsh covering, and techniques to generate CDMA spread spectrum communication signals. The disclosure in that patent, i.e. U.S. patent 5,103,459, is also hereby fully incorporated by reference into the present application. Further, the present invention may utilize 20 time multiplexing of data and various principles related to “high data rate” communication systems, and the present invention can be used in a “high data rate” communication systems, disclosed in U.S. patent application entitled “Method and Apparatus for High Rate Packet Data Transmission” Serial No. 08/963,386 filed on November 3, 1997, and assigned to the assignee of the present invention. The 25 disclosure in that patent application is also hereby fully incorporated by reference into

the present application.

Referring back to Figure 3, graph 300 shows power axis 301 plotted against time axis 302. Aggregate voice power P_v 304 for all the voice users within the cell is shown in graph 300 as solid curve 304. Aggregate voice power P_v 304 varies in time
5 as shown in graph 300. Voice power limit $P_{v,\max}$ 306 is the maximum voice power allocated for the aggregate of voice signal transmissions. Voice power limit $P_{v,\max}$ 306 is shown in graph 300 as horizontal double-dotted-dashed line 306. Extra voice power is allocated in addition to aggregate voice power P_v 304, so that the total voice power transmitted at any time is substantially equal to voice power limit $P_{v,\max}$ 306. The extra voice power, which “fills in” the gap between P_v 304 and $P_{v,\max}$ 306, can be provided, for example, by transmitting some additional information which is encoded using orthogonal codes just as if the additional power were being provided for additional users. In the embodiment shown in Figure 3, no useful information is transmitted, so the extra voice power is transmitted as artificial noise. It is manifest that useful information can be transmitted using the extra voice power, the details of which are apparent to a person of ordinary skill in the art, and thus are not described here. The artificial noise is shown in Figure 3 as voice noise power 308, and also indicated with the word “noise.” Voice noise power 308 is encoded using, for example, orthogonal codes as if voice noise power 308 originated as an ordinary user
20 signal. Thus, other users within the cell can still recover their own signal using spread spectrum despreading techniques such as orthogonal codes despite added voice noise power 308. In other words, the users within the cell are “protected” from voice noise power 308 by the use of orthogonal codes or PN codes or other means of spreading voice noise power 308.

JO
DRAFT
15

$P_{v,max}$ 306 for transmission of data bursts 310, 312, and 314. Total power P_{v+d} 316 is the total of aggregate voice power P_v 304 plus the power allocated for voice noise power 308 plus the power allocated for transmission of data bursts 310, 312, and 314.

Thus, total power P_{v+d} 316 may also be stated as the total of $P_{v,max}$ 306 plus the power
5 allocated for data burst transmissions. Data power P_{data} 324 is the power used for transmission of data bursts 310, 312, and 314. Thus, by definition:

$$P_{v+d} = P_{data} + P_{v,max}.$$

Total power P_{v+d} 316 is shown in graph 300 as dotted-dashed, stepped line 316. Total power P_{v+d} 316 varies in time as shown in graph 300. The maximum available signal transmission power that can be allocated for the total of aggregate voice, artificial noise, and data transmissions is maximum total power limit P_{max} 318, shown in graph 300 as horizontal solid line 318 and also indicated by “ P_{max} ”. As seen in graph 300, P_{v+d} 316 remains below maximum power limit P_{max} 318.

As discussed above, transmission of data signals typically occurs in bursts, in contrast to transmission of voice signals, where the average power level for a number of users is relatively even. Thus, relatively large amounts of data are transmitted in bursts at high bit rates separated by periods of relative inactivity, or quiet, in which the data bit rate is low or data transmission ceases entirely. For example, after data burst 310 and before data burst 312, and again after data burst 312 and before data burst
20 314, there is no data available for transmission, i.e. there are gaps in the data transmission. In order to prevent total power P_{v+d} 316 from suddenly dropping, additional data power is transmitted when there are gaps in data transmission to maintain the power consumed by data transmission, data power P_{data} 324, at a desired level. Accordingly, total power P_{v+d} 316 is maintained at a desired level.

25 The additional data power, which “fills in” the gap between data burst 310 and

data burst 312, and the gap between data burst 312 and data burst 314, can be provided, for example, by transmitting some additional information which is encoded using orthogonal codes just as if the additional power were being provided for additional data users. In the embodiment shown in Figure 3, no useful data is
5 transmitted, so the additional data power is transmitted as artificial noise or dummy data. The artificial noise is shown in Figure 3 as data noise 320, and data noise 322. Data noise 320 and data noise 322 are encoded, for example, using orthogonal codes as if data noise 320 and data noise 322 originated as ordinary data signals. Thus, users within the cell can still demodulate their own signals without undue interference from data noise 320 and data noise 322. In other words, the users within the cell are “protected” from data noise 320 and data noise 322 by the use of orthogonal codes or PN codes or other means of spreading data noise 320 and data noise 322.

10 15 20 25

Figure 3 shows an example interaction of mixed voice and data signal transmission with power control in accordance with one embodiment. The amount of data power, P_{data} 324, allocated to data burst 310 is controlled as a percentage of voice power limit $P_{v, max}$ 306 rather than allocating the full amount of power which might be required to transmit data burst 310 as quickly as possible. For initial data burst 310, P_{data} 324 is limited, for example, to 10% of $P_{v, max}$ 306. Then, for example, for subsequent data burst 312, P_{data} 324 is increased or adjusted upward by pre-determined amounts of 5% of $P_{v, max}$ 306 as required to transmit the data at a reasonable rate. For example, P_{data} 324 can be increased subject to specific conditions relating to the amount of data noise and actual data that have recently been transmitted. For example, the condition can be that the actual data transmitted, i.e. the amount of data transmitted in data burst 310, is 95% or more of the total power transmitted and that
20 25 the data noise transmitted is 5% or less of the total power transmitted. Conversely,

P_{data} 324 can be decreased or adjusted downward by pre-determined amounts, for example, when the actual data transmitted is 50% or less of the total power transmitted and the data noise transmitted is 50% or more of the total power transmitted. In general, the pre-determined and pre-defined amounts for the 5 adjustments can be any amounts between 0% and approximately 15%; 5% and 10% are used only as examples for illustrative purposes. For subsequent data burst 314, no further adjustments of P_{data} 324 are required. As seen in the equation $P_{v+d} = P_{data} + P_v$,
max, total power P_{v+d} 316 is limited by the pre-determined increases in P_{data} 324.

As shown in Figure 3, filling $P_{v, max}$ 306 with voice noise 308; increasing total power P_{v+d} 316 by pre-determined amounts; and filling in P_{v+d} 316 by inserting data noise such as data noise 320 between consecutive data bursts 310 and 312 have the effect of eliminating large swings, overshoots, and instability in the allocation of aggregate voice power P_v 304. For example, filling in P_{v+d} 316 by inserting data noise such as data noise 320 between consecutive data bursts 310 and 312 prevents the overreactions of the power control system to large sudden changes in data power level, discussed in connection with Figure 1, by eliminating such large sudden changes when there are gaps in the data transmission. As a result, aggregate voice power P_v 304 changes smoothly. Increasing total power P_{v+d} 316 by pre-determined amounts also results in eliminating large sudden changes when there are transitions 20 from “quiet periods” to transmitting data bursts or when there are large increases in the rate or amount of data being transmitted by the communication system. Moreover, filling $P_{v, max}$ 306 with voice noise 308 prevents the feedback effect between cells discussed in connection with Figure 2 by keeping the voice power, “seen” by other cells as noise, at a constant level, i.e. $P_{v, max}$ 306. Keeping the voice power at a 25 constant level further prevents large swings in the voice power, such as those seen in

Figure 2C, and thus prevents reactions of neighboring cells to those swings. As a result, the intra-cell power control problems discussed above in connection with Figure 1 are avoided, and the inter-cell power control problems discussed above in connection with Figure 2 are also avoided.

5 Figure 4 illustrates another example of power control in a CDMA communication system in accordance with one embodiment. Figure 4 shows graph 400, having power axis 401 plotted against time axis 402. Aggregate voice power P_v 404 for all voice users within the cell is shown in graph 400 as solid curve 404. Aggregate voice power P_v 404 varies in time as shown in graph 400. Voice power limit $P_{v,max}$ 406 is the maximum voice power allocated for the aggregate of voice signal transmissions. Voice power limit $P_{v,max}$ 406 is shown in graph 400 as double-dotted-dashed, stepped line 406. Extra voice power is allocated in addition to aggregate voice power P_v 404, so that the total voice power transmitted at any time is substantially equal to voice power limit $P_{v,max}$ 406. The extra voice power is voice noise power 408, which “fills in” the gap between P_v 404 and $P_{v,max}$ 406. As discussed above, voice noise power 408 is typically provided by transmitting artificial noise which is coded or spread the same way as other user signals so that the users within a cell can recover their own signal using spread spectrum despreading techniques despite added voice noise power 408.

20 When no useful information is transmitted using voice noise power 408, it is to the advantage of the system to minimize the amount of power consumed by voice noise power 408. Figure 4 shows an example of adapting voice power limit $P_{v,max}$ 406 in accordance with one embodiment. Adapting voice power limit $P_{v,max}$ 406 has the effect of reducing the amount of power consumed by transmission of voice noise power 408, for example, in comparison with voice noise power 308 in the example

shown in Figure 3. Adaptation of voice power limit $P_{v, \max}$ 406 can be achieved in many ways. For example, voice power limit $P_{v, \max}$ 406 can be adjusted to pre-set levels in response to a change in usage in order to reflect periods of greater or lesser usage. Usage can be measured according to various criteria. For example, usage can
 5 be measured as the percentage utilization of the total system capacity based on the number of users actually using the system at a particular time compared to the maximum number of users the system can accommodate. As another example, usage can be measured as the percentage utilization of available transmit power by comparing the value of aggregate voice power P_v 404 to the value of maximum power limit P_{\max} 418, described below. The response to change in usage can be dynamic, or the response can be scheduled for certain times of day. Voice power limit $P_{v, \max}$ 406 can be set to a higher limit at the beginning of a “busy hour”, for example, and then reset to a lower limit at the end of the busy hour.

Continuing with Figure 4, power is allocated in addition to voice power limit $P_{v,\max}$ 406 for transmission of data bursts 410, 412, and 414. Total power P_{v+d} 416 is the total of aggregate voice power P_v 404 plus the power allocated for voice noise power 408 plus the power allocated for transmission of data bursts 410, 412, and 414.

Thus, total power P_{v+d} 416 may also be stated as the total of $P_{v, \max}$ 406 plus the power allocated for data burst transmissions. Data power P_{data} 424 is the power used for
 20 transmission of data bursts 410, 412, and 414. Thus, by definition:

$$P_{v+d} = P_{\text{data}} + P_{v, \max}.$$

Total power P_{v+d} 416 is shown in graph 400 as dotted-dashed, stepped line 416. Total power P_{v+d} 416 varies in time as shown in graph 400. The maximum available signal transmission power that can be allocated for the total of aggregate voice, artificial
 25 noise, and data transmissions is maximum total power limit P_{\max} 418, shown in graph

400 as horizontal solid line 418 and also indicated by “ P_{max} ”. As seen in graph 400, P_{v+d} 416 remains below maximum power limit P_{max} 418.

As discussed above, transmission of data typically occurs in bursts. In order to prevent total power P_{v+d} 416 from suddenly dropping, additional data power is
5 transmitted when there are gaps in the data transmission to maintain the power consumed by data transmission, data power P_{data} 424, at a desired level. Accordingly, total power P_{v+d} 416 is maintained at a desired level. The additional data power, which “fills in” the gap between data burst 410 and data burst 412, and the gap between data burst 412 and data burst 414, is data noise 420 and data noise 422. As discussed above, data noise 420 and data noise 422 can be provided by transmitting artificial noise or dummy data, which is coded or spread the same way as other user data signals. Thus, the users within the cell can recover their own signal using spread spectrum despreading techniques despite added data noise 420 and data noise 422.

Figure 4 also shows an example interaction of mixed voice and data signal transmission with power control in accordance with one embodiment. The amount of data power, P_{data} 424, allocated to data burst 410 is controlled as a percentage of voice power limit $P_{v,max}$ 406 rather than allocating the full amount of power which might be required to transmit data burst 410 as quickly as possible. For initial data burst 410, P_{data} 424 is limited, for example, to 10% of $P_{v,max}$ 406. Then, for example, for
20 subsequent data burst 412, P_{data} 424 is increased by pre-determined amounts of 5% of $P_{v,max}$ 406 as required to transmit the data at a reasonable rate. For example, P_{data} 424 can be increased subject to specific conditions relating the amount of data noise and actual data that have recently been transmitted. For example, the condition can be that the actual data transmitted, i.e. the amount of data transmitted in data burst 410, is
25 95% or more of the total power transmitted and that the data noise transmitted is 5%

or less of the total power transmitted. In general, the pre-determined and pre-defined amounts for the adjustments can be any amounts between 0% and approximately 15%; 5% and 10% are used only as examples for illustrative purposes. For subsequent data burst 414, no further adjustments of P_{data} 424 are required. As seen in the equation 5 $P_{v+d} = P_{\text{data}} + P_{v, \text{max}}$, total power P_{v+d} 416 is limited by the pre-determined increases in both P_{data} 424 and $P_{v, \text{max}}$ 406.

15

As shown in Figure 4, adapting voice power limit $P_{v, \text{max}}$ 406; filling $P_{v, \text{max}}$ 406 with voice noise 408; increasing total power P_{v+d} 416 by pre-determined amounts; and filling in P_{v+d} 416 by inserting data noise such as data noise 420 between consecutive data bursts 410 and 412 have the effect of eliminating large swings, overshoots, and instability in the allocation of aggregate voice power P_v 404. For example, filling in P_{v+d} 416 by inserting data noise such as data noise 420 between consecutive data bursts 410 and 412 prevents the overreactions of the power control system to large sudden changes in data power level, discussed in connection with Figure 1, by eliminating such large sudden changes when there are gaps in the data transmission. As a result, aggregate voice power P_v 404 changes smoothly. Increasing total power P_{v+d} 416 by pre-determined amounts also results in eliminating large sudden changes when there are transitions from “quiet periods” to transmitting data bursts or when there are large increases in the rate or amount of data being transmitted by the 20 communication system. Moreover, filling $P_{v, \text{max}}$ 406 with voice noise 408 prevents the feedback effect between cells discussed in connection with Figure 2 by limiting the voice power, “seen” by other cells as noise, to slow, smooth, gradual changes, i.e. $P_{v, \text{max}}$ 406 is constrained to pre-defined adjustments. Limiting the voice power to gradual changes further prevents large swings in the voice power, such as those seen 25 in Figure 2C, and thus prevents reactions of neighboring cells to those swings.

As a result, the intra-cell power control problems discussed above in connection with Figure 1 are avoided, and the inter-cell power control problems discussed above in connection with Figure 2 are also avoided. Furthermore, adaptation of voice power limit $P_{v, \max}$ 406 improves the efficiency and the economy 5 of power control in the communication system by minimizing the amount of extra power used for voice noise filling.

Figure 5 illustrates a further example of power control in a CDMA communication system in accordance with one embodiment. Figure 5 shows graph 500, having power axis 501 plotted against time axis 502. Aggregate voice power P_v 504 for all voice users within the cell is shown in graph 500 as solid curve 504. Aggregate voice power P_v 504 varies in time as shown in graph 500. Voice power limit $P_{v,\max}$ 506 is the maximum voice power allocated for the aggregate of voice signal transmissions. Voice power limit $P_{v, \max}$ 506 is shown in graph 500 as double-dotted-dashed, stepped line 506. Extra voice power is allocated in addition to aggregate voice power P_v 504, so that the total voice power transmitted at any time is substantially equal to voice power limit $P_{v, \max}$ 506. The extra voice power is voice noise power 508, which “fills in” the gap between P_v 504 and $P_{v, \max}$ 506. As discussed above, voice noise power 508 is typically provided by transmitting artificial noise, which is coded or spread the same way as other user signals. Thus, the users 20 within a cell can recover their own signal using spread spectrum despreading techniques despite added voice noise power 508.

When no useful information is transmitted using voice noise power 508, it is to the advantage of the system to minimize the amount of power consumed by voice noise power 508. Figure 5 shows an example of adapting voice power limit $P_{v, \max}$ 506 25 in accordance with one embodiment. Adapting voice power limit $P_{v, \max}$ 506 has the

effect of reducing the amount of power consumed by transmission of voice noise power 508 in comparison with the case in which a voice power limit, such as voice power limit $P_{v,\max}$ 306 shown in Figure 3, is not adapted. Adaptation of voice power limit $P_{v,\max}$ 506 can be achieved in many ways. For example, voice power limit $P_{v,\max}$ 506 can be adjusted to pre-set levels in response to a change in usage or at certain times of the day in order to reflect periods of greater or lesser usage. Voice power limit $P_{v,\max}$ 506 can be set to a higher limit at the beginning of a “busy hour”, for example, and then reset to a lower limit at the end of the busy hour.

Continuing with Figure 5, power is allocated in addition to voice power limit $P_{v,\max}$ 506 for transmission of data bursts 510, 512, and 514. Total power P_{v+d} 516 is the total of aggregate voice power P_v 504 plus the power allocated for voice noise power 508 plus the power allocated for transmission of data bursts 510, 512, and 514. Thus, total power P_{v+d} 516 may also be stated as the total of $P_{v,\max}$ 506 plus the power allocated for data burst transmissions. Data power P_{data} 524 is the power used for transmission of data bursts 510, 512, and 514. Thus, by definition:

$$P_{v+d} = P_{data} + P_{v,\max}.$$

Total power P_{v+d} 516 is shown in graph 500 as dotted-dashed, stepped line 516. Total power P_{v+d} 516 varies in time as shown in graph 500. The maximum available signal transmission power that can be allocated for the total of aggregate voice, artificial noise, and data transmissions is maximum total power limit P_{max} 518, shown in graph 500 as horizontal solid line 518 and also indicated by “ P_{max} ”. As seen in graph 500, P_{v+d} 516 remains below maximum power limit P_{max} 518.

As discussed above, transmission of data typically occurs in bursts. In order to prevent total power P_{v+d} 516 from suddenly dropping, additional data power is transmitted when there are gaps in the data transmission to maintain the power

consumed by data transmission, data power P_{data} 524, at a desired level. Accordingly, total power P_{v+d} 516 is maintained at a desired level. The additional data power, which “fills in” the gap between data burst 510 and data burst 512, is data noise 520. Similarly, data noise 522 is transmitted to maintain the level of total power P_{v+d} 516
5 after the end of data burst 512, although there is no data burst transmitted subsequent to the transmission of data noise 522. It is wasteful, however, to continue transmission of data noise 522 for very long if there is no subsequent data to transmit or if the data transmission rate has fallen low enough that substantially less power should be allocated to data transmission. In other words, data power P_{data} 524 should be reduced or adjusted to a lower level.

Therefore, data noise 522 is transmitted subject to specific conditions relating the amount of data noise and actual data that have recently been transmitted. For example, the condition can be that the data noise transmitted is equal to or greater than the actual data transmitted. Then, if the amount of data noise 522 is equal to or greater than the amount of data transmitted in data burst 512, then data power P_{data} 524 will be reduced or decreased by a pre-determined amount to a lower level. For example, the pre-determined amount can be equal to 10% of voice power limit $P_{v, max}$ 506. Figure 5 shows data noise 523 transmitted at a level of data power P_{data} 524, which is reduce by 10% of voice power limit $P_{v, max}$ 506 from the level of data noise 522. In general, the pre-determined and pre-defined amounts for the adjustments can be any amounts between 0% and approximately 15%, and 5% and 10% are used as examples only for illustrative purposes.

As no further data is transmitted, data power P_{data} 524 continues to be reduced, for example, by a pre-determined amount equal to 10% of voice power limit $P_{v, max}$ 506 for each reduction, during the transmission of data noise 523. Thus, the example

in Figure 5 shows a “stepped” appearance for data noise 523. In addition, the example of Figure 5 shows voice power limit $P_{v, \max}$ 506 being reduced by amounts equal to approximately 10% of voice power limit $P_{v, \max}$ 506 during the transmission of data noise 523. Thus, total power P_{v+d} 516, which is the sum of data power P_{data} 524 and voice power limit $P_{v, \max}$ 506, is shown in graph 500 as decreasing during the transmission of data noise 523 in response to both the reductions in voice power and in data power. As seen in the equation $P_{v+d} = P_{\text{data}} + P_{v, \max}$, total power P_{v+d} 516 is limited by the pre-determined decreases in both P_{data} 524 and $P_{v, \max}$ 506.

Data noise 520, data noise 522, and data noise 523 can be provided by transmitting artificial noise or dummy data, which is coded or spread the same way as other user data signals, as discussed above. Thus, the users within the cell can recover their own signals using spread spectrum despreading techniques despite added data noise 520, data noise 522, and data noise 523.

As shown in Figure 5, adapting voice power limit $P_{v, \max}$ 506; filling $P_{v, \max}$ 506 with voice noise 508; reducing data power P_{data} 524 in pre-determined amounts; and filling in P_{v+d} 516 by inserting data noise such as data noise 520 between consecutive data bursts 510 and 512 or by inserting data noise such as data noise 523 when reducing data power P_{data} 524 have the effect of eliminating large swings, overshoots, and instability in the allocation of aggregate voice power P_v 504. For example, filling 20 in P_{v+d} 516 by inserting data noise such as data noise 520 between consecutive data bursts 510 and 512 prevents the overreactions of the power control system to large sudden changes in data power level, discussed in connection with Figure 1, by eliminating such large sudden changes when there are gaps in the data transmission. As a result, aggregate voice power P_v 504 changes smoothly. Reducing total power 25 P_{v+d} 516 by pre-determined amounts also results in eliminating large sudden changes

when there are transitions from transmitting data bursts to “quiet periods” or when there are large decreases in the rate or amount of data being transmitted by the communication system. Moreover, filling $P_{v, \max}$ 506 with voice noise 508 prevents the feedback effect between cells discussed in connection with Figure 2 by limiting 5 the voice power, “seen” by other cells as noise, to slow, smooth, gradual changes, i.e. $P_{v, \max}$ 506 is constrained to pre-defined adjustments. Limiting the voice power to gradual changes further prevents large swings in the voice power, such as those seen in Figure 2C, and thus prevents reactions of neighboring cells to those swings.

As a result, the intra-cell power control problems discussed above in connection with Figure 1 are avoided, and the inter-cell power control problems discussed above in connection with Figure 2 are also avoided. Furthermore, adaptation of voice power limit $P_{v, \max}$ 506 improves the efficiency and the economy of power control in the communication system by minimizing the amount of extra power used for voice noise filling. In addition, limiting and reducing data power P_{data} 524, improves the efficiency and the economy of power control in the communication system by minimizing the amount of extra power used for data noise filling.

It is appreciated by the above detailed disclosure that the invention provides a method and system of power control for mixed voice and data transmissions in a CDMA communication system. Although the invention is described as applied to 20 communications in a CDMA system, it will be readily apparent to a person of ordinary skill in the art how to apply the invention in similar situations where power control for mixed voice and data signal transmission is needed.

From the above description, it is manifest that various techniques can be used for implementing the concepts of the present invention without departing from its 25 scope. Moreover, while the invention has been described with specific reference to

certain embodiments, a person of ordinary skill in the art would recognize that changes can be made in form and detail without departing from the spirit and the scope of the invention. For example, the voice noise filling presented in one embodiment described here can be omitted so that data power is allocated directly on
5 top of voice power without departing from the method of data noise filling and smoothly allocating data power presented in one embodiment described here. Also, for example, different techniques can be employed for measuring interference, transmitting artificial voice noise and artificial data noise, and adjusting the power allocated to the transmitted signal. Further, the type of information used for voice noise and data noise filling and the type of coding or spreading used may differ from that presented in one embodiment described here. The described embodiments are to be considered in all respects as illustrative and not restrictive. It should also be understood that the invention is not limited to the particular embodiments described herein, but is capable of many rearrangements, modifications, and substitutions without departing from the scope of the invention.

Thus, a method for power control for mixed voice and data transmission has been described.

WHAT IS CLAIMED IS:

“我就是想說，你這個人，真該死！”
